Hydrodynamic instabilities are of crucial importance in describing many phenomena, from very large scales such as stellar explosions (supernovae) to very small scales, such as inertial confinement fusion (ICF) implosions. Such mixing causes overturn of massive stellar cores in supernovae, and affect attempts at ICF ignition. The Rayleigh-Taylor (RT) instability occurs at an accelerated interface between two fluids with the lower density accelerating the higher density fluid, and the Richtmyer-Meshkov (RM) instability occurs when a shock wave passes an interface between the two fluids of different density. Buoyancy causes ``bubbles" of the light fluid to penetrate the denser fluid, while ``spikes" of the heavy fluid penetrate the lighter fluid. In the deep nonlinear regime, this interpenetration evolves into turbulent mixing which has been notoriously difficult to predict quantitatively. With realistic multi-mode initial conditions, in the deep nonlinear regime, the mixing zone width, h, and its internal structure, progress through an inverse cascade of spatial scales, reaching an asymptotic self-similar evolution: $h=\alpha_{RT}Agt^2$ for RT and $h=\alpha_{RM}t^{\theta}$ for RM. While this characteristic behavior has been known for about 30 years, the self-similar parameters α_{RT} and θ_{RM} and their dependence on dimensionality and density ratio have continued to be intensively studied and a relatively wide distribution of those values have emerged. This talk will describe the 30 years "research slalom" in search of a unified and compact description of this turbulent mixing evolution that shed light on the spread in α_{RT} and θ_{RM} [1]. Results of experiments performed in the last year using NIF (under the Discovery Science program) for quantitative testing of this theoretical advance will be presented. Complementary experiments, which are planned to take place in the coming year, will be discussed.
